Resurvey of Sceloporus localities in Mexico

From 2002-2008, we resurveyed localities for *Sceloporus* lizard species, at sites previously described in the literature or based on our own field studies from 1980-1995. We specifically excluded any cases of extinction where habitat modification was the cause and only included sites characterized by intact habitat as described in historical surveys. We quadrupled sampling effort (hours × personnel) relative to past surveys in cases of putative extinction events to ensure that we minimized registration of false extinction records. *Sceloporus* lizards are heliophilic ectotherms and quite conspicuous during morning hours when they bask and engage in elaborate push-up displays, which enhances the probability of detection, especially during the breeding season when we conducted field surveys. Thus, erroneous extinction events are unlikely compared to other lizard species that have cryptic activity patterns. We resurveyed 46 species at 200 localities. We registered a total of 24 extinctions, or 12% of all populations surveyed (Table S1).

Phylogenetic inference in the Phrynosomatidae

Because species with adjacent ranges might be related phylogenetically, we used methods of phylogenetic independent contrasts (PIC) to determine associations among extinction risk, geography, climate and thermal adaptations like viviparity and T_b. We mapped extinctions on a phylogeny to account for phylogenetic structure in the pattern of extinctions (Figure S2). Phylogeny used for mapping extinctions was based on based on a Sceloporine super tree (*S1*) and phylogenies for subclades (*S2, S3*). We obtained most of the data for the T_b of *Sceloporus* from Andrew's (*S4*) review, but we also included Garrick's (*S5*) T_b measure for *S. cyanogenys* (the control values), as well as our own measurements.

We also used a phylogeny for the Phrynosomatidae to reconstruct evolutionary changes in the Critical Thermal Maximum (*S6*), CT_{max}, as a function of T_b. For CT_{max} and T_b of the Phrynosomatidae, we used data from Table S4 for T_b of *Sceloporus* and reviewed additional data in the literature for T_b and CT_{max} across the Phrynosomatidae (*S7*-*S22*). The phylogeny is based on the Sceloporine super tree (*S1*) and phylogenies for subclades (*S23*), and a more recent Phrynosomatidae phylogeny that includes evolutionary branch lengths based on 2 mtDNA genes and 5 nuclear genes (*S24*). This recent phylogeny confirms the topology of the Sceloporine super tree based on diverse genetic data (*S1*). We computed phylogenetic independent contrasts (PIC) (Figure S4) using the PDAP (*S25*) module of Mesquite (*S26*) and branch lengths are based on the Phrynosomatidae phylogeny (*S24*).

Details on Yucatán ground-truth and the thermal physiological model of extinction

Thermal models designed to mimic thermal properties of basking lizards estimate operative model temperatures, T_e [(*S27*) PVC pipe size, 2.5×15cm, grey primer paint to match reflectance of *S. serrifer*], were connected to a HOBOTEMP™ and deployed at 4 sites in the Yucatán. We recorded average model temperature, T_e, every h over a 4-month period (Jan-May). Geographical coordinates of the ground-truth for persistent (Izamal, Conkal) and extinct sites (Chumpan, Uxmal) in the interior of the Yucatán peninsula are: Izamal, Yucatán, 20° 53' 48.2" N; 88° 47' 10.4" W, 22m elevation; Conkal, Yucatán, 21° 03' 46.1" N; 89° 32' 09.2" W, 9 m elev.; Chumpan, Campeche, 18° 12' 42.3" N; 91° 30' 45.7" W, 10m elev.; and Uxmal, Yucatán, 20° 27' 37.2" N; 89° 44' 38.7" W, and 47m elev. Three weather stations (Mérida, Valladolid, Chetumal see Fig. S5) are close to the sites. A plot of the change in T_{max} over the last 36 years at these stations is shown for the months of January to May (Fig S5). A total of 14 of 15 station×months registered significant increases in T_{max}. The four *S. serrifer* sites in our ground-truth of extinction and thermal physiology are closest to the Mérida weather station. We used temperature records from the Mérida station (Jan-Apr 2009) to compute the functional relationship between h_r in activity time, which is the cumulative h each day when $T_e > \mathrm{T}_{b\ preferred}$ ($\mathrm{T}_{b\ preferred}$ =31°C for *S. serrifer*) (Fig. 4B). We related h_r on a daily basis to the T_{max} observed at Mérida on a daily basis and fitted the following highly significant linear regression equation (Figure S4B):

$$h_r[T_e > T_{b\ preferred}] = slope \times (T_{max}) + intercept1 \qquad \text{(Equation S1).}$$

This equation has a high goodness-of-fit to a linear equation with no evidence of non-linearity (e.g., quadratic or cubic terms). Notice that if we standardize Eqn. S1 in terms of $T_{b\ preferred}$ (e.g., where $T_{max} - T_{b,\ preferred}$ is the x-variate) before carrying out the model fit we obtain a more general equation for lizards:

$$h_r[T_e > T_{b\ preferred}] = slope \times (T_{max} - T_{b,\ preferred}) + intercept2 \qquad \text{(Equation S2).}$$

Given data on $T_{b,\ preferred}$, Equation S2 can be extended to any species of lizard. Data on $T_{b\ preferred}$ is actually quite rare, because it requires measurement in a laboratory thermal gradient under standard conditions (*S28*). However, measurements of activity body temperatures (T_b), which are highly correlated with $T_{b\ preferred}$ *(S28)*, are available for almost all of the species in our extinction survey and T_b is highly correlated with extinction (T_b is also highly correlated with $T_{b\ preferred}$, see analysis Table S6). To extend our physiological model of extinction to other *Sceloporus* we substituted T_b from Table S4 for $T_{b\ preferred}$. When a T_b value for a species was unavailable, we used nearest ancestor reconstruction to estimate values (only a few species required ancestor reconstruction, c.f., species listed in Table S1 *vs.* Table S4). Figure S4A suggests a value of $h_r \sim 4$ h (March-April average), based on persistent *S. serrifer* populations that are on the verge of extinction. We explored this assumption by varying h_r from 1 to 12 h in 0.1 h increments to compute the overall fit of the model (e.g., deviations of extinction model from observed data). Based on this statistical estimation procedure, a value of h_r =3.85 h provides the best fit between observed and predicted extinctions. This calibration suggests that a value of h_r =3.85 h during critical reproductive periods may be general for heliothermic *Sceloporus* species. In the future, this assumption could be tested by exploring other factors known to influence T_e and thermal activity limits such as body size, habitat preference, and perch height (*S27, S28*) and with T_e estimates of other species located at sites on the verge of extinction. Nevertheless, the goodness-of-fit of the model in predicting extinctions is exceptional (see text). We also varied the two critical months used to compute h_r, but March and April provided the best fit for both reproductive modes. This is intuitively appealing because if it gets too hot early in the season, it will be exceptionally hot in May-July and thus only the early season h_r (i.e., critical period of reproduction) sends a population to the tipping point of extinction.

It might be more appropriate to compute the cumulative hours T_e exceeds CT_{max} (Fig. S4C). However, CT_{max} values are rarely reported in the primary literature (N=11, Table S5) compared to T_b values (N=26, Table S4). Moreover, T_{max} recorded at weather stations, which is the most widely reported measure of environmental temperature in climate databases, rarely exceeded CT_{max} values (Fig. S4C), thus potentially generating large errors of inference in relating h_r to T_{max}-CT_{max}. In contrast, T_{max} often exceeds T_b, providing residuals (e.g., T_{max} - T_b, Fig. S4BC) for estimating a functional relationship with h_r. Thus, the relationship between T_b - T_{max} (Equation S2) performs well in predicting extinction, while CT_{max} - T_{max} performs poorly. Finally CT_{max} is correlated with T_b in PIC regression analysis (Table S5, Fig. S7).

A Physiological model for extinction risk and T_b and global climate models of T_{max}

i. Overview of the Global Simulation Model

We used global climate surfaces from the WORLDCLIM web site (*S30*) (www.worldclim.org) (for the years 1975, 2020, 2050, 2080) to derive T_{max} (°C) at a given latitude and longitude (10-arc minute resolution). We also used WORLDCLIM predictions for T_{max} in the year 2050 and 2080 under three scenarios for climate change (IPPC 3rd Assessment). We ran CCCMA, HADCM3, and CSIRO for both a2a scenarios and results were qualitatively similar. We present CCCMA a2a simulations in Figure 3. To compute extinction surfaces (Fig. 3), we varied T_b from 28-40°C in 1°C increments, as a function of T_{max} observed at a given latitude and longitude with a 10-arc minute resolution (e.g., WORLDCLIM database). Besides these simulations, we used an iterative procedure to estimate h_r, the critical threshold for extinction for each family (described in detail below), based on extant distributions of lizards (in 1975, before the onset of climate change), T_{max} and T_b. In Figure 3, we present extinction surfaces for h_r =4.55 h, $\bar{h}_{restriction}$ for all heliothermic lizard families computed using a best-fit criterion described below. We computed cell averages at a 2-min resolution for presentation in contour plots (Fig. 3). We varied latitude from 70° N to 60° S. Given T_{max}, T_b and Equation S2 relating T_{max}-T_b to the activity threshold for extinction, if $h_r = 0.74\times(T_{max}-T_b)+6.1$ exceeds h_r for a given family, the population/species at that site was assumed to go extinct. We varied the critical months for the reproductive period with latitude to allow for shortening of breeding periods and later breeding from equatorial to temperate climate zones (*S31*), which is the general pattern for lizards across the globe. We also varied climate effects on timing of reproduction (described in detail below). We wrote simulation code for all extinction models in R (*S32*).

ii. Simulation details on critical months for T_{max} and extinction risk as a function of latitude

The key parameter that varies with latitude is the months of the year when h_r governs risk of extinction. In the Mexican *Sceloporus* data (15-34 N° Latitude), which spans the wet-dry climatic zone to northern temperate climatic zone, our analyses show that the months of March and April were critical for oviparous and viviparous lizards. After these months, temperatures skyrocket (e.g., May, June, July) and thus restrictions in activity time become even more severe. Thus, these two months were used to predict extinction risk specifically because they indicate climate has passed a tipping point that can no longer sustain the demography of a species with a given T_b. Development of models specific to oviparous vs. viviparous lizards has very little impact on simulation results (not shown), because T_b accounts for most extinction risk differences due to mode of reproduction (Fig. 1C). For lizards at temperate zone latitudes higher than Mexico (>24°), breeding seasons are shifted northwards by 1 month for every 12° of Latitude. In the wet-dry tropical zone of southern Mexico and Central America (and similar regions in other parts of the world; e.g., 12-24° N or S), lizards can breed potentially over a 5- to 6-month period that coincides with wet seasons. In our model, we assumed the breeding period during which too great an h_r results in extinction varies with latitude in 3 distinct climatic zones: 12 months in the equatorial zone, 5-6 months in the wet-dry tropics, and 2 months in the temperate zone.

This generates a somewhat conservative set of extinction predictions among equatorial regions for the following reasons. In the wet-dry tropical zone (12-28° N and S), we assumed conservatively that the threshold h_r in activity period for extinction would have to be exceeded across the entire 5-6 month wet season period (June-October in the northern hemisphere, mid-December-May in the southern hemisphere). In equatorial regions (12° N-12° S latitude) there are two distinct wet and dry seasons per year (as the sun passes over the equator during each of the two equinoxes) (*S31*) so lizards can potentially breed in any month of the year depending on annual fluctuations. We assumed conservatively that the threshold restriction in activity time (h_r) would have to be exceeded, on average, across the entire 12 months of the year. Despite these conservative assumptions for the months in which h_r in activity time must occur, our model predicted high rates of extinction in the wet-dry tropics and equatorial zones. We also relaxed this conservative assumption and computed h_r over the 9 hottest months in the equatorial zone. To develop smooth transitions across the 3 discrete climate zones (equatorial: 12° N or S, wet-dry tropics: 12-24° N or S, temperate: > 24° N or S), we assumed a latitudinal gradient in the contribution of months to extinction risk between equatorial and wet-dry tropical zones of ±2° of latitude (e.g., gradient between the two climate zones applied across 10-14° latitude), and a similar ±2° gradient between the wet-dry tropical zone and temperate zone (e.g., gradient between the two climate zones applied across 22-26° latitude). Varying the size of this gradient between climate zones had little impact on qualitative predictions of the global model. Across the temperate zone (24-60°) we assumed that breeding months shifted in a smooth latitudinal gradient (12° latitude per 1-month shift in critical months) such that for 60° N/S latitude and higher, critical months were June-July, while at 24° N/S Latitude critical months were March-April (e.g., México). In North America the species *Anota* (= *Phrynosoma*) *hernandesi* reaches 55° N/S Latitude in Alberta, Canada. In South America, *Liolaemus bibroni* reaches 51° S in southern Patagonia. In Eurasia *Lacerta vivipara* reaches latitudes above the Arctic Circle in Finland (up to 69° N). Accordingly, we ran our simulations from 70° N to 60° S latitudes (with a 10 arc-sec resolution).

We also modeled impacts of the evolution of earlier reproductive periods on extinction risk by compressing the start of the critical period of temperate zone lizards by 1 month for the highest latitudes (>50° N/S) and proportionately less between 24° N/S and 55° N/S). This actually enhanced extinction risk slightly because warming across the globe is predicted to be more rapid in spring months than summer (c.f., historical patterns for México). Thus, there is no temporal escape from global warming extinction.

In simulations, we assumed that lizards were limited to < 4500 m (e.g., elevation record for *Liolaemus alticolor* in the Andes, Table S7A). Lizards may exceed this value in the future, given current climate trends. We did not vary the effect of altitude on lay date, and this may have a small effect on the predictions of our model. Our model also does not include dispersal. However, Mexican ground-truth data indicates that ignoring northward movement will have a negligible effect on the species extinction dynamic. In México, northern dispersal corridors are rapidly cut off, given the accelerated pace of climate change, and the only refuge will be at high elevation. However, as we show in the paper, competition from expanding low elevation species will drive extinction of endemic species restricted to high elevation refuges. Before climate change began, high elevation endemic species were typically restricted to one mountain range in México. Thus, the extinction projections for México predict a near parity between levels of population extinction and levels of actual species extinctions (see paper). Similar patterns of montane endemism of lizards are found across the globe.

iii. Checking the model based on the WORLDCLIM database against the NOAA dataset

The WORLDCLIM website does not supply historical reconstructions of T_{max} from 1975-2009. Accordingly, we cross-validated our computation of T_{max} in 2009 at each geographical location (e.g., interpolation of T_{max} in 2009, from WORLDCLIM data in 1975 and 2020) using temperature trend surfaces available from NOAA (www.noaa.gov). The highest resolution NOAA maps for historical temperature trends (300 km smoothing) generate large blocks of missing data. Accordingly, we used NOAA maps with a 1200 km smoothing radius, which provided good coverage. Furthermore, the NOAA site does not supply T_{max} but does supply $T_{average}$ and we converted $T_{average}$ to T_{max} using regression models for WORLDCLIM climate surface data, which supplies both. We used NOAA data as a cross check for WORLDCLIM data. We also validated both of these global databases with European Climate Assessment data, with our database of 99 Mexican stations, and Australian Meterological databases (see below).

iv. Testing the model with geo-referenced T_b data on all the lizard families

We computed which populations (geo-referenced T_b data, Table S6) are currently undergoing extinction (e.g., T_{max} value for 2009 interpolated from WORLDCLIM database for 1975 and 2020). Even though the simulation model estimates incidence in 1975 (described below) for the computation of extinction (in 2009, 2050, 2080) the model does not completely describe incidence of lizard populations due to low environmental temperatures. Some low temperature sites may be unoccupied because they are too cool. Many other climate simulations (see refs in text) also do not take into account distributions of T_b adaptations across the globe. While other researchers have simulated site incidence by first estimating a climate envelop to determine physiological tolerances, and then simulating incidence at a given site, we overcame the "site incidence" problem by computing extinctions from a large sample of geo-referenced lizard sites with known T_b, latitude and longitude (e.g., N=1216 geo-referenced T_b values, Table S6). We present simulation surfaces for extinctions in Figure 2, and extinction summaries from geo-referenced T_b data in Table 1 of the paper.

The utility of our model for computing extinctions is easiest to visualize in equatorial regions (12°S-12°N Lat, Fig. 3). The thermal adaptation T_b has a large effect on incidence in 1975. In 1975, heliothermic lizards with a $T_b \leq 29$°C would not have been present at many equatorial sites and thus would not have been present to go extinct (by 2009, 2050, 2080). By 2080 nearly all Saharan heliothermic lizard populations with $T_b \leq 32$°C or $T_b \leq 35$°C will be extinct, even lizards with $35 < T_b \leq 38$°C. In summary, high T_b is a thermal adaptation that allows lizards to inhabit hot climates, but climate change will ultimately begin to affect all lizard families, even those with the highest evolved T_b. Notice that the global extinction model predicts lizard extinctions in Mexico for the period 1975-2009 (Fig. 2A, e.g., for viviparous lizards with $T_b < 32$°C), and the global model matches predictions for Mexico (2050, 2080).

<u>iv. Modifications of the extinction model for heliothermic versus thermoconforming lizard families</u>

Our model of extinction risk was developed for heliothermic lizards that must bask to maintain temperature (or retreat if it gets too hot which limits activity). For heliothermic families of the world, we estimated h_r for each lizard family using a best-fit procedure similar to Mexican *Sceloporus* lizards. In 1975, all sites should be computed as persistent (e.g., before the onset of climate change), given the T_b expressed by each population. In some heliothermic families a fraction of the populations were able to persist at certain sites despite a high computed h_r (see Table 1 for values for each family) at that site. One hypothesis that might explain this pattern is that these populations have evolved additional adaptations (e.g., behavioral plasticity, habitat preference) besides high T_b that allow them to endure a very high h_r in activity during the breeding season (e.g., burrows or other refuges that might allow the lizards to forage even during hot weather, large size and thermal inertia). We used a best-fit procedure to estimate h_r for each family to refine the model. We estimated h_r for each family such that 95% of populations (95% c.l.) in each family would be extant, while only 5% would be extinct in 1975. This assumption also reflects 5% uncertainty we have in computed values for populations when using fitted WORLDCLIM surfaces applying to a given lizard site. This procedure of calibrating such thermal climate spaces for h_r in each family based on T_b (and T_{max} in 1975) yielded an h_r for the Phrynosomatidae of 3.92 h, which compares very favorably with the value of h_r=3.85 estimated directly for *Sceloporus* spp. (Phrynosomatidae) from extinction data (see paper), or the value of h_r=4 estimated directly from the length of time per day when $T_e > T_b$ as assessed by thermal models deployed at extant sites on the verge of extinction (see *Details on Yucatán ground-truth and the thermal physiological model of extinction*). This is an important cross-validation of 1975 climate envelops based on T_b and h_r and application to extinction projections. The use of a 95% c.l. also has another interpretation. During normal climate excursions (i.e., before onset of anthropogenic change, before 1975), some populations may have been on the verge of extinction due to normal evolutionary processes. Anthropogenic climate change and the rapid rise in T_{max} exacerbated this natural process of extinction among meta-populations. We used such populations "on the verge of extinction" to estimate a 95% c.l. for h_r of each family. We present estimates of h_r by family and estimates of $\overline{T}_{\max}$ by family in Table 1.

Interestingly, h_r and $\overline{T}_{\max}$ by family are correlated with $\overline{T}_b$ for each family (PICs, Fig. S7) suggesting that both adaptations evolve in response to local environments [we used the phylogeny from (*S33*) in our PIC analysis of the families of the world]. Notice that our model explicitly incorporates a negative relationship (i.e., trade-off) between h_r and $\overline{T}_b$ (e.g., equation S2). In summary, our model accounts for evolved changes in T_b and h_r, observed prior to climate induced extinctions (e.g., computed from distributional limits in 1975), to predict extinctions (e.g., from 1975 to 2009, 2050, 2080).

The model requires a very simple modification for thermoconformers (non-basking lizards). In computing the best-fit h_r extinction threshold by family, we used the same calibration developed for heliotherms (e.g., from the extant distribution of lizards in 1975 and 95% c.l. on extinction and h_r by family). Because thermoconformers are close to T_{air} during the day, if $T_{air}<T_{preferred}$, we computed h_r in activity as the time that a thermoconformer can be out and active provided that $T_{air}<T_b$. We computed the daily temperature excursions in T_{air} between T_{min} and T_{max} (downloaded from the WORLDCLIM website for the years 2000, 2050, 2080) and assuming a sine wave for T_{air} with amplitude 24 h. We assumed that if thermoconformers had to retreat for $>h_{r,\ family}$ h/d when $T_{air}>T_b$, the species at that geo-referenced location would go extinct. Interestingly, thermoconformers have higher best-fit h_r than heliotherms, but heliotherms compensate by evolving a higher T_b (Fig. S8). As noted above, h_r and T_b are inversely related in our physiological model (Eqn. S2). The model will apply to thermoconformers, which on average have a much lower T_b than heliotherms (see Table S6), but thermoconformers are adapted to life deep inside tropical forests [refs (S*147-150; S344-347*) in Table S6], while heliotherms are adapted to life in the open. Huey et al. (see ref. *31* and discussion in paper) conjectured that thermoconformers should be more likely to go extinct than heliotherms. We found that the extinction probability of heliotherms was the same as thermoconformers when we conducted the test in a phylogenetic context (Fig. S8) largely because extant thermoconformers and heliotherms inhabit different habitats, but climate warming in each habitat type makes lizards of both thermoregulatory modes equally susceptible to extinction.

Extinction probability is also similar for heliotherms and thermoconformers because heliotherms inhabit many equatorial and regions (e.g., Saharan and sub-Saharan Africa) that are impossible for thermoconformers to inhabit (historically or present day), and these areas elevate extinction risk for heliotherms. A surprising model prediction is the severity of climate change extinction regardless of adaptations such as T_b and thermoregulatory mode of thermoconformers versus heliotherms, unless the T_b of a lizard species is very high (e.g., $35 < T_b \leq 38$°C) such as the Teiidae (Table 1). Other lizards like the Liolaemidae inhabit extremely high altitude environments (Andes) and are unlikely to go extinct (Table 1). However, some Liolaemidae are entirely viviparous (*Phymaturus*) and have high extinction risk.

We include estimates of extinction and h_r for all families, even nocturnal and fossorial families. The model should apply to fossorial families like the Anniellidae, Pygopodidae, or nocturnal Gekkota familes (see Table S6) with some caveats on the interpretation of what is estimated by h_r by family.

Fossorial forms have the highest h_r (Table 1), which is related to a thermal refuge in soil. Gekkota include both diurnal heliotherms, nocturnal thermoconformers and fossorial forms (e.g., Pygopodidae). We did not partition the Gekkota families in Table 1 by diurnal versus nocturnal species. Nevertheless, nocturnal Gekkota can thermoregulate during the day [see (S*118, S126, S127, S328*) in *Literature cited*] and the model should apply to these species. Nocturnal species also have a high h_r for the same reason as fossorial species, but their thermal refuge involves a shift to night-time activity. Nevertheless, climate change in T_{max} will raise nightly T_{min} as climate warms, resulting in extinctions of nocturnal species. The extinction model should also apply to large-bodied families (Varanidae, Helodermatidae, Iguanidae) that can have considerable thermal inertia and low T_b achieved at night can buffer high T_b excursions during the day. In this case h_r (fitted from the 1975 distribution) takes into account the large body size of these families, which remains unexplained by T_b (e.g., Eqn S2). Other families like the Scincidae include some fossorial species, but most T_b data were for heliotherms and most skinks bask (based on 210 populations/species, Table S6). Nevertheless T_{soil} will warm as T_{max} warms due to climate change, resulting in extinction of some fossorial skinks. Thus, the model we have developed should apply to all lizards, but may require extinction validations for fossorial, nocturnal and large bodied species/families, as we have done for heliotherms and some thermoconformers (see paper). The best-fit routines used to estimate h_r from 1975 climate surfaces of T_{max} (and T_{min} in the case of thermoconformers) along with the geographical distribution of T_b (N=1216 sites) is a powerful tool for modeling climate envelopes for taxa. A simple interpretation for h_r is that it reflects the residual difference in extinction risk that remains unexplained by extinction risk as predicted by differences between T_{max}-T_b. It also has a physiological interpretation that is related to demographic collapse – exceeding the critical h_r due to global warming begins the process of demographic collapse that culminates in extinction.

v. Global Patterns of Temperature Variation used to parameterize the extinction model

Geo-referenced data [latitude, longitude, elevation (m)] for T_b (N=1372) were obtained from the literature for 34 lizard families. We searched Google Scholar using the name of each lizard family or genera in each family and the words preferred temperature, body temperature, T_b, or cloacal temperature.

We used historical and revised nomenclature for each family/genus (old nomenclature is in brackets following the reference, Table S6). We included multiple records of single species, given that T_b's were recorded across a variety of habitats, latitudes and elevations. Thus, our extinction modeling is based on N=587 species T_b's geo-referenced (N=1216 locations) by latitude, longitude and elevation. In T_b analyses, we included measures of $T_{b,preferred}$ with T_b, given that these values were highly correlated in taxa where both have been measured (R^2=0.587, $F_{1,151}$=210.34, P<0.00001). In studies where multiple sites were listed, we included the average T_b across all sites, or if T_b was partitioned by site in the source, we used the average T_b for each site. In our Google Scholar search we strived to obtain broad taxonomic coverage (across all lizard families and genera) and geographic coverage of the world (see map of sites, Fig. S9). The latitude, longitude and altitude for each entry were derived from each source (coordinates or verbal descriptions) that were mapped and verified with Google Earth. In a few instances the sources did not provide exact coordinates for all T_b values and supplementary refs (listed below) were used. In one source (ref. *S184*, see literature cited) no geo-referencing was provided for the T_b data, however, supplementary materials in that source provided geo-referencing for DNA samples so we assumed these were also the source of T_bs. Approximately 50% of T_b records are from the New World, and the data set has reasonable coverage from temperature to tropical zones, but species diversity is under-represented in the tropics. Accordingly, we computed estimates of extinction weighted by $N_{species}$ in each family (Table 1) to provide unbiased estimates of extinction, assuming a random sample of lizard T_b in each family.

Summary of extinction in the biotas in South America, Europe, Africa and Australia

Synopsis. We used published records (*S34*) of local extinction in South America and we resurveyed all sites. We also used historical records to measure local extinctions in Europe (*S35-S43*) and we resurveyed all sites. In Europe, we used the European Climate Assessment database (*S44*) to validate data from the WORLDCLIM database (*S30*). For Africa, the historical records were more sparse but we found a number articles using Google Scholar searches of focal taxa, mainly from resurveys of National Parks and Game Reserves (*S45-S54*). We estimated h_r for each of these databases from a large sample of georeferenced sites (see below), but in the case of *Liolaemus lutzae* we could validate h_r with behavioral observations (*S45-S56*) (see Table S7A). For Australia, we used published records of local extinctions that have been detected in the past two decades (*S57-S66*). We validated WORLDCLIM surfaces (*S44*) with Australian Government Bureau of Meteorology data (http://www.bom.gov.au/climate/averages/). A map of the sites used in the validation of extinction across five continents is presented in figure S9.

South America. We assembled data on N=3155 Liolaemidae sites in South America from Herpnet.org (N=426) and our surveys, including data from resurveys of N=129 sites (Table S7A). Resurveys of geo-referenced locations for determining extinction status of Liolaemidae species confirms the spatial precision of our model predictions (χ^2=31.778, d.f.=1, P<0.001, Table S7A). The model pinpoints extinction status of *L. lutzae* (coastal) and *Phymaturus tenebrosus* (interior Patagonia). In contrast, other Liolaemidae species are not predicted to go extinct because of their cooler microclimates (low T_{max}), higher T_b or both. The model also precisely predicts observed extinctions (*S34*) among 24 *L. lutzae* populations (χ^2=10.35, d.f.=1, P<0.0001, Table S7A). Analysis of N=3155 sites confirms that current (as of 2009) local extinctions in Liolaemidae are averaging 3.7%, close to the global average. The sites in our Liolaemidae dataset span -11ºS to -54ºS and are only missing data at the equatorial region where the global average extinction rate is projected to be slightly higher at 5%, based on the projections presented in Table 1 (see also values in the text).

Europe. European extinctions are based on N=46 resurveyed sites of *Lacerta vivipara*. The distribution of this species spans from the mountain ranges overlooking the Mediterranean to the Arctic Circle and from Spain to Japan. Our 2002-2009 resurveys include most southern sites (*S35-S43*) in Europe that are at risk of extinction. Extinctions of European common lizards are concentrated in a low elevation and low altitude band in southern Europe. Europe has experienced a rapid rise in T_{max} in the past decade and our linear approximations using worldclim.org do not adequately capture the rate of warming in Europe. Consequently, we used data from the European Climate Assessment database (*S44*), which has a continuous record of T_{max} for 324 European weather stations, to compute deviations from our linear interpolation of Worldclim.org data (c.f., Mexican climate surface, Fig. 1) so as to refine data on T_{max}. The refined data on T_{max} resulted in high concordance between observed and predicted extinctions (N=46, Table S7B, χ^2= 24.4, d.f.=1, P<0.00001). We also ran a model with N=117 sites distributed throughout Europe to estimate those clades of *L. vivipara* predicted to be extinct by 2009 (χ^2= 32.0, d.f.=1, P<0.001). This included southern literature records (*S35-S41*) and northern sites as far as the Arctic Circle.

Africa. We assembled data for two endemic lizard families in Africa: Gerrhosauridae + Cordylidae based on N=165 sites from Herpnet.org for mainland Africa and N=122 from ref (*S45*) and Herpnet.org for Malagasy Gerrhosauridae. The extinction model predicts only a single location out N=165 geo-referenced sites that should exhibit local extinction in Africa, and this location is registered as locally extinct (*S46*) in recent resurveys (exact p-value=0.006). Extant status in other areas was also assessed from resurvey work across Africa (refs. *S42, S47-S52*). These resurveys list 64 species×sites for Gerrhosauridae + Cordylidae (e.g., slightly smaller database of species and sites) and only a single local extinction was recorded (e.g., *S46*, listed above), which also exactly matched the model predictions (exact p-value=0.015). The model predicts that 2009 extinctions of Gerrhosauridae on the island of Madagascar should be much higher (23%). Two recent squamate re-surveys of two protected sites (e.g., Reserves) in Madagascar report local extinction rates of 44% (*S53*) and 19% (*S54*), respectively in squamate species (i.e. 21% on average). Our model predicts that susceptible species in the families Gerrhosauridae, Opluridae, Chamaeleonidae, and diurnal Gekkota should be going extinct in 2009 (Table 1) but also suggests that other taxa with low extinction risk should still be extant in these resurveys (e.g., nocturnal Gekkota). The observed extinctions of Malagasy lizards conforms to this expectation, thus the model predictions of extinctions are also validated by 2009 local extinctions in Madagascar. Assessing the current extinctions in Africa was hampered by sparse primary surveys (pre-1990). Despite availability of only a few resurveyed sites, the quantitative fit of our model to observed extinctions validates the patterns for Africa and Madagascar.

Australia: Two species in the *Egernia* Group (= *Ergenia* + *Liopholis*) are going extinct at sites in the Great Desert. Our model exactly predicts the 3 observed extinctions in *Liopholis slateri* and 8 sites where it persists (χ^2=12.9, d.f.=1, P<0.0001). We also compared *L. slateri* to other *Egernia* Group spp. in Table S7C, none of which currently face extinction (goodness of fit χ^2=17.8, d.f.=1, P<0.0001). Additional analysis of N=2481 sites indicates that only *Egernia* Group spp. sympatric with *L. slateri* currently face extinction, such as the Great Desert Skink, *L. kintorei*. We analyzed extinction of *L. kintorei* and found a significant association between observed and predicted extinctions (goodness of fit χ^2=3.93, d.f.=1. P=0.047, Table S7D), though there are areas in which there is a lack of fit (discussed in Table S7D).

General methods for global survey databases and sensitivity analyses of model to T_b plasticity

Our choice of families and regional lizard biotas used in the global validation of the extinction model was based on three criteria: i) taxa with extensive sampling of T_b data (Table S6), ii) taxa with high spatial density of geo-referenced coordinates to generate high-resolution spatial maps of extinction, and iii) taxa that have been the focus of recent resurveys (e.g., 1990-2009) since the onset of global warming in 1975. These data are required to parameterize the extinction model for any given species/taxon. The final parameter, h_r, can be estimated given a large sample of georeferenced coordinates (see paper) for a given species, genus, or family. Of all the lizard families around the world besides the Phrynosomatidae, the Liolaemidae (South America), Lacertidae (Europe), Scincidae (Australia and in particular the *Egernia* Group), and to a lesser extent the Cordylidae + Gerrhosauridae (Africa), satisfied these criteria. Nevertheless, recent Malagasy reptile resurveys provide good data on recent local extinctions, despite the sparse nature of T_b data for Malagasy lizard (Table S6). In situations where T_b was unavailable for a given species (i.e., Table S6) we used two approaches to estimate T_b: (i) the generic average T_b for unsampled species or (ii) we estimated geographic variation in T_b where sampling was sufficient to estimate a significant altitudinal or latitudinal effect on T_b. For example there was a significant altitudinal effect on T_b of *L. vivipara* (P<0.0001, Table S6) and a significant altitudinal effect on the T_b of the Liolaemidae (P<0.0001, Table S6). Using the predicted T_b from these regression equations generated similar extinction patterns as using generic averages for missing data.

In Europe and South America, the observations of extinctions vs. persistence are based on resurveys of sites visited by us and other researchers (e.g., literature accounts). However, we supplement these primary observations on extinction with data we downloaded from Herpnet.org. For example on January 21, 2010 we downloaded N=8249 records for *Liolaemus spp*. and N=334 records for *Phymaturus spp*., which we distilled to a unique set of N=426 geo-referenced populations. We defined a unique population to be separated by 1 km from other unique populations. We supplemented Herpnet records (public domain) with our collections for a grand-total of 3155 Liolaemid unique sites. For Scincidae in Australia, we focused on *Egernia* Group *spp*. (*Egernia* + *Liopholis*) that are densely sampled across the range and have already registered local extinctions (*Liopholis slateri* and *L. kintorei*, *S57-S66*). For the *Egernia* Group *spp*. we downloaded N=5643 records, which we distilled to N=1476 unique georeferenced sites from Herpnet combined with records from other Australian Museums to yield N=2841. We also analyzed a smaller set of sites specifically resurveyed before and after 1990, which included the *L. slateri* and *L. kintorei* sites. For Africa, we used Herpnet to download records for Gerrhosauridae + Cordylidae (N=165), and we used records in ref (*S45*) for Malagasy Gerrhosauridae. We supplemented these records from the Port Elizabeth Museum and Transvaal Museum and personal captures (AMB) for a total of N=1646 unique sites. In all work, we focused on sites with intact habitat and excluded disturbed sites. For example in Africa, we focused attention on recent herpetological survey data in National Parks and Game Reserves (*S46-S52*). In all African resurvey work (described in detail, above) only a single site has registered a local extinction [ref (*S46*), *Gerrhosaurus flavigularis*). To compute extinct vs. persistence in Madagascar we relied on two park surveys that reported observed local extinctions (*S53, S54*), and the exact number of local extinctions of species in several distinct plots allowing us to compute observed extinctions for thermoconforming (21% observed local extinction) and heliothermic species (21% observed local extinction) of lizards in the same habitat (see results and sample sizes reported in paper).

Resurvey data (Tables S7A-D) provide resolution on exact sites that have locally extinct versus persistent populations. While the larger datasets do not provide resolution on extinctions, they provide excellent resolution on the calibration of h_r from extant distributions of a species in 1975, before the onset of climate change (c.f., method used in the paper for geo-referenced T_b data). Thus, we estimated h_r more precisely for a given genus, as we did with the *Sceloporus* of Mexico, and used this value in extinction predictions. Otherwise, the model is exactly the same as that used in global extinction predictions. We used lay dates as assumed in the global model, except in the case of *Lacerta vivipara* and *Phymaturus spp*., which have coincidentally evolved a summer lay period that has elevated extinction risk in both groups. Comprehensive treatments of extinction datasets for each continent are forthcoming.

Plasticity in T_b. We used multiple T_b records for single species (e.g., *Uta stansburiana* has 30 records) and genera to test sensitivity of model predictions to T_b plasticity. The analysis assumes that the highest T_b registered for a given species can be reached by behavioral plasticity at all sites and this might ameliorate extinction risk. However, the highest T_bs are usually registered at the hottest sites that face high current and future risk, whereas low T_bs have been registered at the coolest sites (e.g., high altitude and high latitude) that have reduced extinction risk (now or in the future). Thus, T_b plasticity has a negligible impact on extinction risk. As already shown in the paper, rates of adaptation are constrained by low h^2.

Computation of the Probability of Species Extinction

For the focal 5 families in our five-continent validation of local population extinction, we could compute the projected levels of species extinction by determining those species in which all local sites will likely go extinct. These computations of species extinction are based on 6354 sites (see *Summary of extinction in the biotas in South America, Europe, Africa and Australia*). We assumed that if an endemic species was lost all sites, that species would go extinct, while for widespread species if 95% of all sites went extinct, we assumed that species would be likely to go extinct (e.g., within the 5% margin of error). Few widespread species are projected to go totally extinct, while many endemics are projected to go totally extinct. We then computed total species extinctions for 2080 for the species in our validation (Table S8). In computing local extinctions for the Liolaemidae we partitioned the analysis into the genus *Phymaturus*, which is entirely viviparous and *Liolaemus*, which is mainly oviparous. We considered the six mtDNA clades of *L. vivipara* to be distinct species, given levels of sequence divergence. The resulting values relating local population extinction to species extinction (Table S8) can be used to derive a highly significant predictive relationship for probability of species extinction by 2080 ($t=16.2$, $P=0.0001$), where the linear relationship was constrained to go through the origin:

$$P(\text{species extinction})_{2080} = 0.912 \times P(\text{local extinction})_{2080} \qquad \text{Equation S3,}$$

and by 2050 ($t=6.33$, $P=0.001$):

$$P(\text{species extinction})_{2050} = 0.352 \times P(\text{local extinction})_{2050} \qquad \text{Equation S4.}$$

We applied these relationships to the values for local population extinction in 2080 and 2050 to derive the probability of species extinction in 2050 and 2080 for lizard families across the globe (Table 1). We weighted the values of total species extinction by the number of species in each family to derive the estimates of global levels of species extinction of 6% in 2050 and 20% in 2080 described in the paper. Therefore, total species extinctions dramatically jump by 2080 relative to values projected for 2050.

Figure S1. A contour plot of $\dot{T}_{\max}$ = the yearly rate of change in T_{max}, at a given weather station (j) for each month. Coefficients for a fitted surface for $\dot{T}_{\max}$ for each month as a function of linear and quadratic terms for latitude and longitude and linear terms for elevation are given in Table S3. Notice the very large increases in $\dot{T}_{\max}$ during winter-spring (Jan-May), and more modest increases during the summer and fall months.

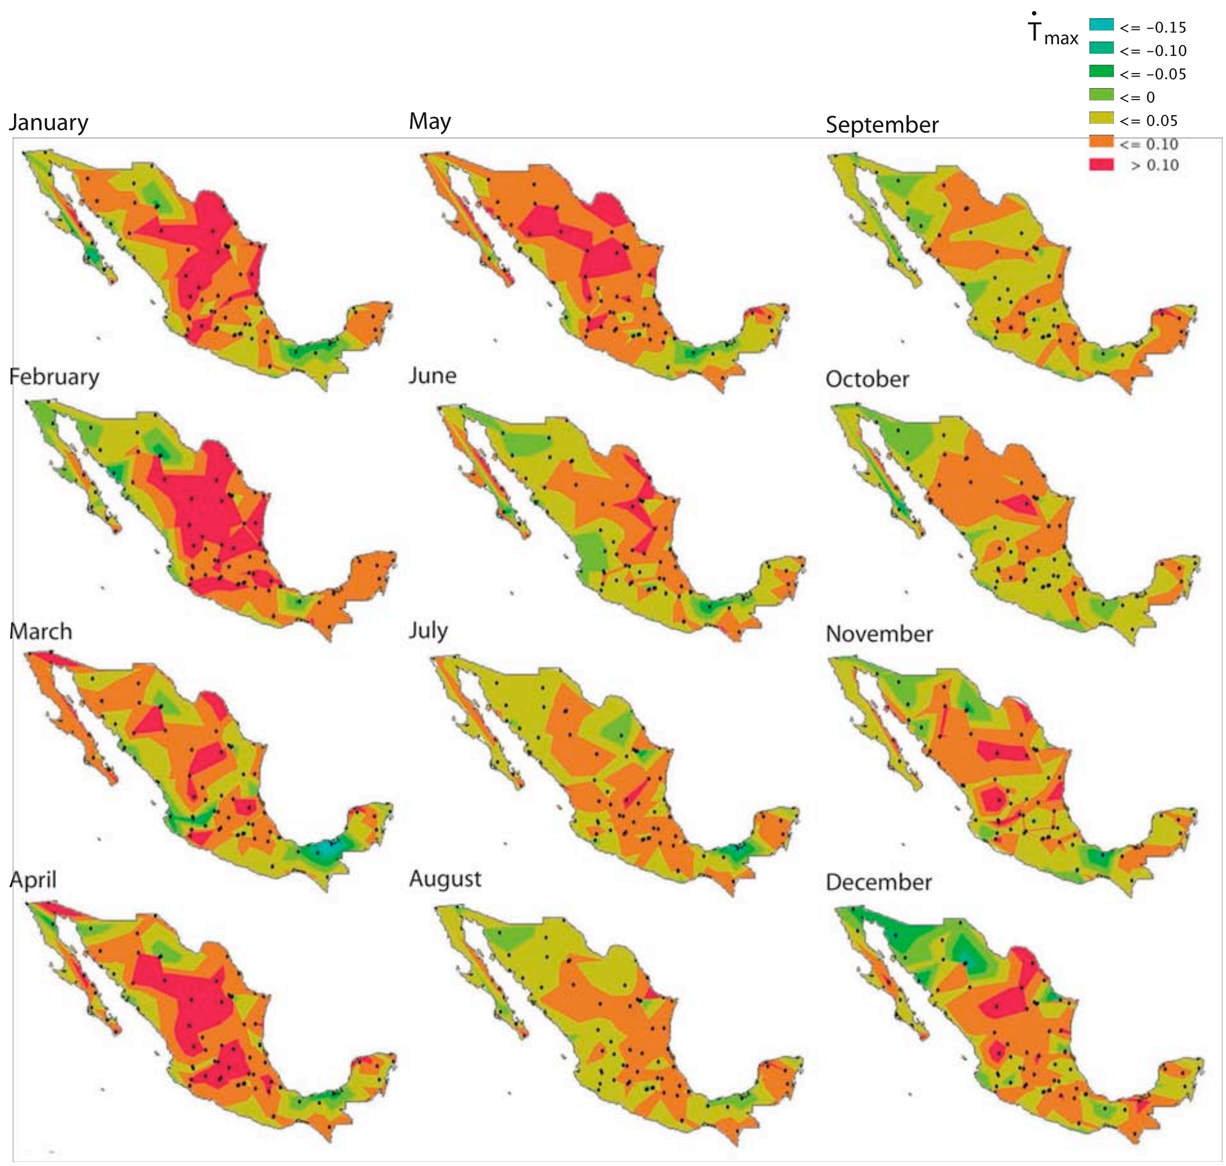

Figure S2. Phylogeny for 48 species of *Sceloporus* lizards (see Table S1 for geographical coordinates). Phylogeny based on a Sceloporine super tree (*S1*) and phylogenies for subclades (*S2, S3*). A recent reanalysis of the *S. spinosus* clade that includes *S. edwardtaylori* yields a similar topology (Calderon unpub. data). The species (delimited by heavy vertical lines) were used to compute the relationship between local population extinction and complete species extinction in the text. (A much larger sample of geo-referenced sites confirms the species extinction analysis based on 200 sites, Sinervo unpublished data). Our samples of the different populations for these *Sceloporus* species are representative of the geographic range of each species.

Figure S3. Phylogeny used for analysis of lineage survival, T_b, T_{air}, and reproductive mode (see Figure Legend S2 for references on phylogeny).

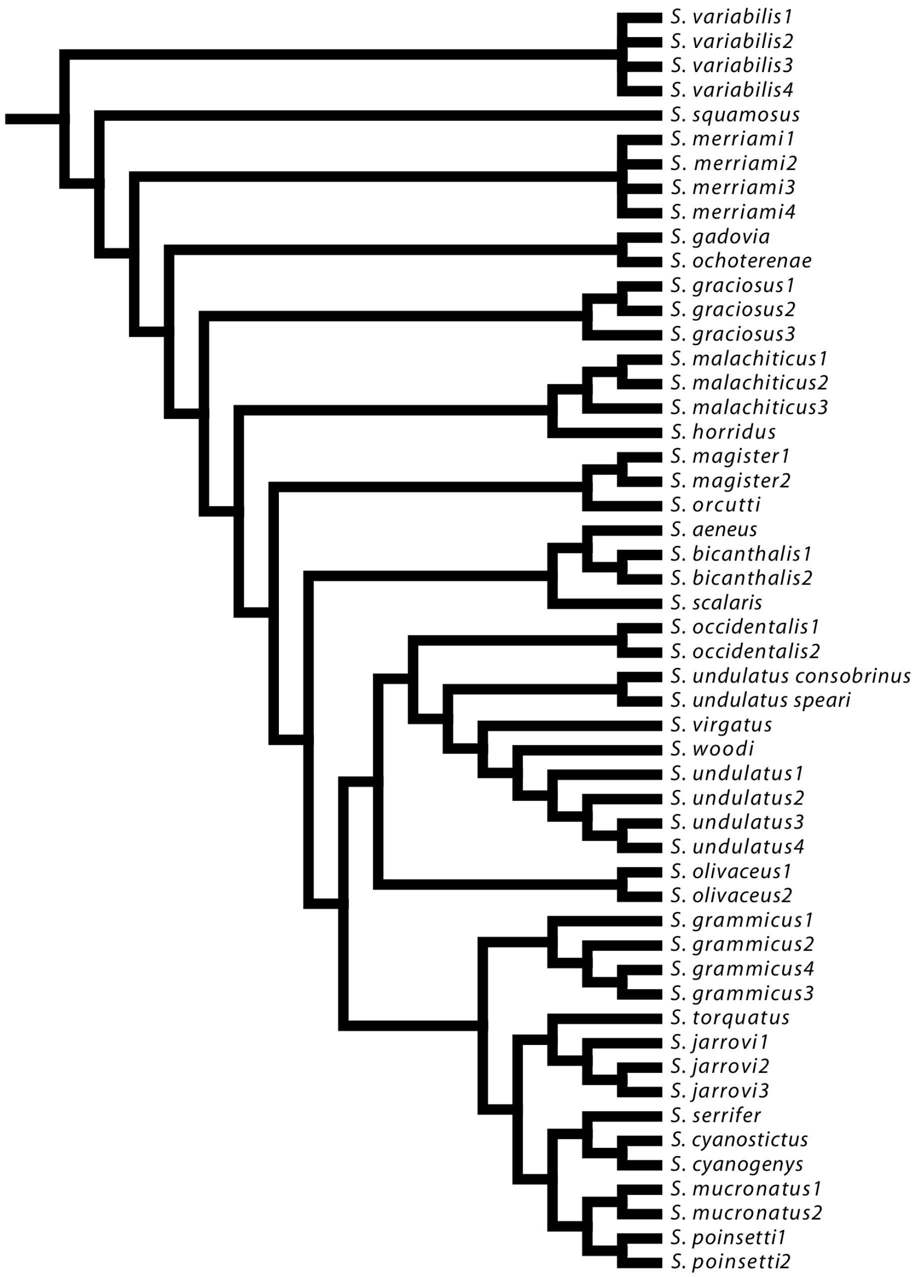

Figure S4. Ground truth for thermal physiology of *Sceloporus serrifer* in the Yucatán peninsula at two extinct and two persistent sites. A) The number of hours of restricted activity, h_r, when T_e exceeded $T_{b\ preferred}$, plotted by month. B) Functional relationship between h_r in activity time and T_{max} registered at the nearby Mérida weather station (e.g., the linear fit to Eqn. S2, above). C) Schematic for the relationship between T_{max} and T_b and their joint effects on h_r in activity (red sections) when lizards cannot be out and active, but must retreat to microclimates. Notice that T_{max} does not have to exceed T_b to restrict activity because heliotherms will typically be greater than ambient T_{air} because they bask in the sun.

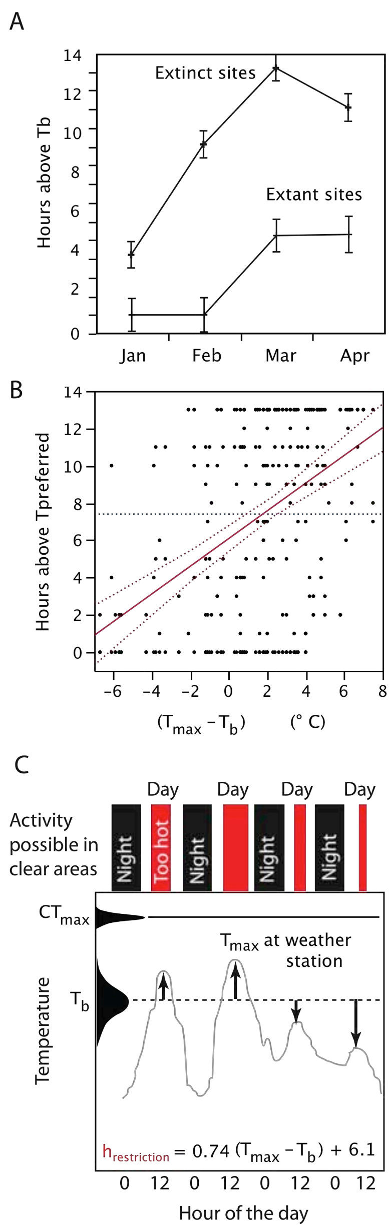

Figure S5 Climate change in the Yucatán peninsula at 3 weather stations near our ground-truth sites of the relationship between extinction, T_e and h_r in activity time for *Sceloporus serrifer.* These weather stations were also near the sites where we deployed lizard models to estimate T_e to ground-truth the relationship between extinction and restriction in activity time.

Figure S6. Phylogeny for 22 species of lizards in the family Phrynosomatidae including 11 *Sceloporus* lizards. We used this phylogeny to reconstruct evolutionary changes in CT_{max} as a function of T_b. This phylogeny is based on the Sceloporine super tree (*S1*) and phylogenies for subclades (*S23*). A more recent phylogeny along with evolutionary branch lengths based on 2 mtDNA genes and 5 nuclear genes (*S24*) confirms our topology of the Sceloporine super tree (*S1*).

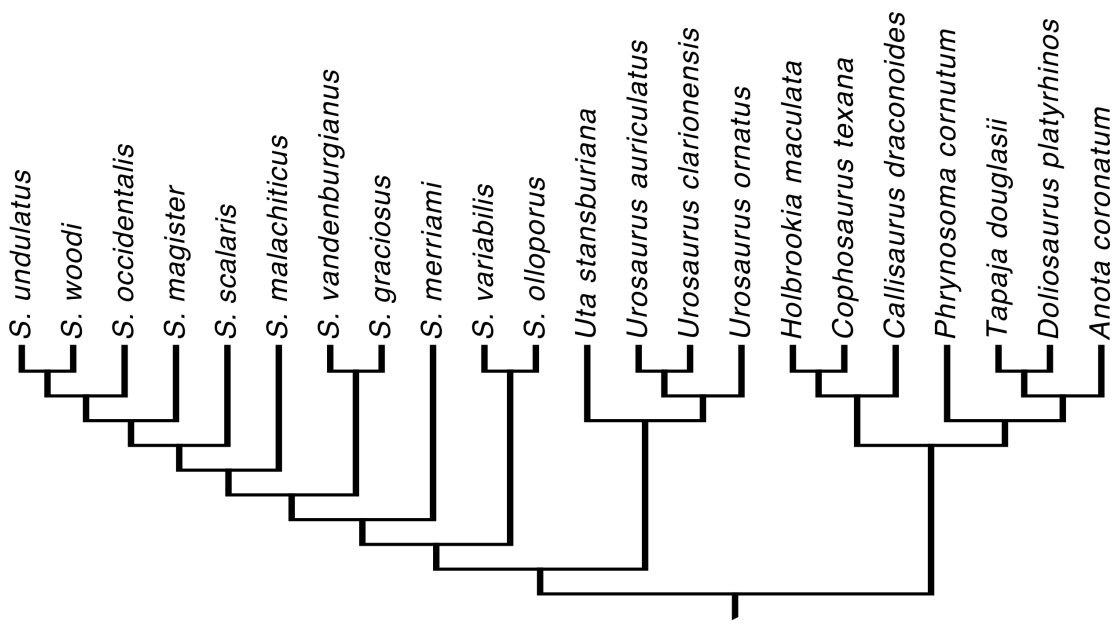

Figure S7. Phylogenetic independent contrasts (standardized) for CT_{max} as a function of contrasts for T_b. The slope of the relationship is 0.51 and this slope is both significantly greater than 0.0 (P<0.02, r = 0.47) and significantly less than a slope of 1.0 (P<0.05).

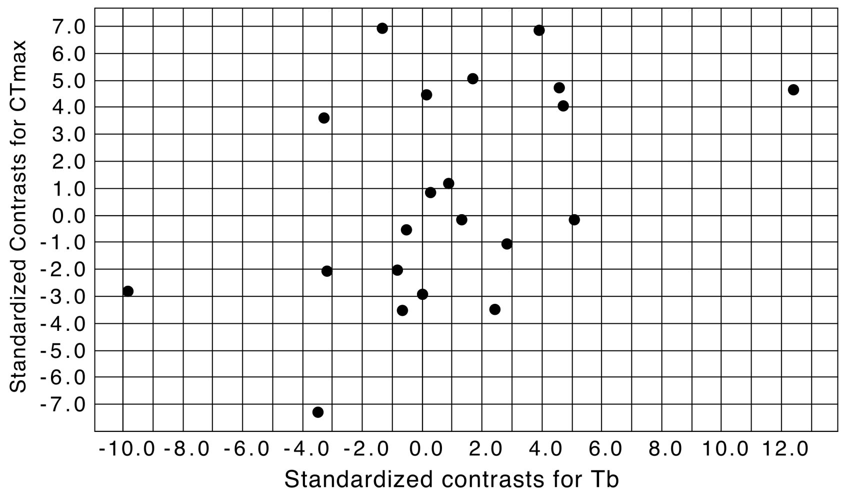

Figure S8. Phylogeny of lizards (S*36*) and reconstruction of thermoregulatory mode using parsimony (*S23*) (thermoconformers – black lines, heliotherms – outlined names). B) PICs of $\bar{T}_b$ as a function of $\bar{T}_{\max}$ (t=3.78, P=0.001), thermoregulatory mode (0 – conformer, 1 – heliotherm; t-value=3.78, P=0.001) and $\ln(\bar{h}_r + 1)$ (t-value=3.78, P=0.001). PIC of extinction risk in 2080 by lizard families as a function of thermoregulatory mode (t-value=2.25, P<0.034), $\bar{T}_b$ (t-value=-4.05, P<0.0005), $\ln(\bar{h}_r + 1)$, t-value=-3.86, P<0.0008], and $\bar{T}_{\max}$ (t-value=5.22, P<0.0001). We pooled the Gekkota into a single value for PIC analysis.

Figure S9. The location of georeferenced T_b samples used to compute extinctions for the 34 lizard families (data from Table S6) are depicted with red dots. The location of the data compiled for the validation of the extinction model on five continents are depicted with black dots.

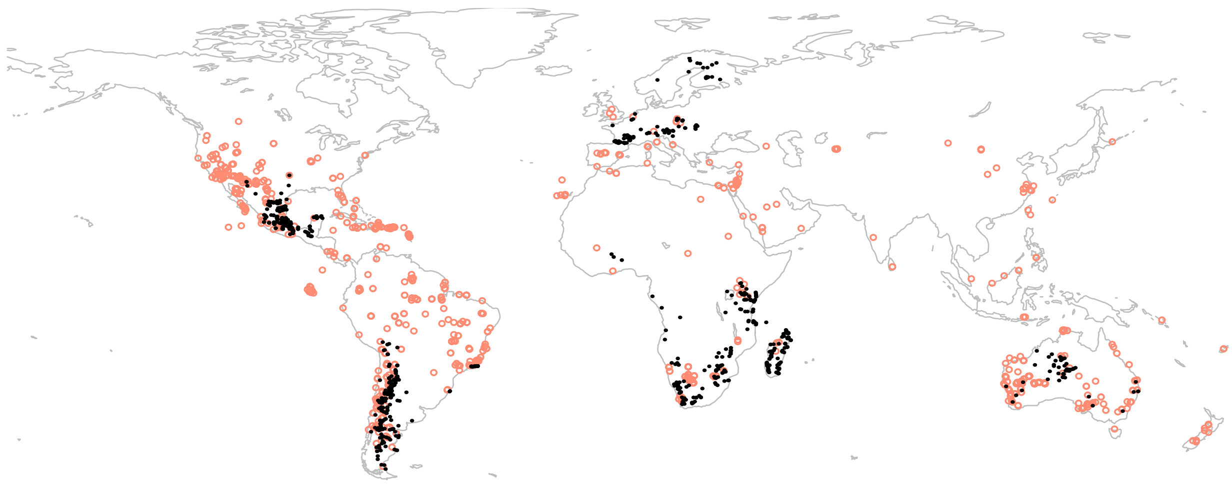

Table S1. The 200 Mexican study sites/species, longitude, latitude, elevation and extinctions since the 1980's. The species name is appended with numbers used to designate sites in studies of phylogeny (Fig S1). In addition to extinctions listed below, range expansions have been recorded since 1996 at the following sites and these sites are also cross-referenced with a given extinct population under the column labeled "Competitor":

(i) *Sceloporus chaneyi* is now very abundant at 2720m relative to Liner's 1973-1974 surveys for the species (Liner, pers. comm.). However, *S. torquatus* is very abundant just below (at 2680m) and *S. chaneyi*, was not at these elevations.

(ii) Extinct *Sceloporus goldmani* at Eje Casita, Carneros and Victoria; *S. parvus* common at all sites.

(iii) Extinct *S. sugillatus* at two sites (1750; 1850 m) that Stanley Fox marked out in 1993-1994 to study territorial behavior of *S. torquatus* and *S. sugillatus*. Only *S. torquatus* is abundant at these two sites.

(iv) *Extinct S. mucronatus* at Chapa de Mota was sympatric with *S. torquatus*, which is now abundant.

(v) *Extinct Sceloporus mucronatus* at Las Minas replaced by range expansion of *S. spinosus* (abundant).

(vi) *Declining - S. mucronatus* at Tecocomulco (2 people × 4 h, 10 lizards); *S. megalepidurus* declining (4 people × 4 h – 2 lizards) 0.125 lizards per h vs. 1.25 10 yrs. ago; Range expansion of *S. torquatus* to site.

(vii) Extinct *S. grammicus LS* clade at Cerro Tolman associated with increase in density of *S. torquatus*.

(viii) Extinct *S. anahuacus* at Albergue (3200 m) replaced by *S. palaciosi* [in 1990 ≤ 3000 m, see (S*2*)].

(ix) Extinct *S. anahuacus* at Albergue (3200 m) associated with range expansion of oviparous *S. aeneus*, which reached the Cantimplora site (3350 m, first seen in 2006, 10 yrs ago it was restricted 350 m lower).

(x) *Sceloporus spinosus* is now in El Chico – a range expansion upwards in elevation.

(xi) *Sceloporus spinosus* E of Casita (near General Cepeda) – range expansion northwards in latitude.

The column "time to maturity" is average time to reproductive maturity, based on literature accounts and elevation, that we assumed in computations of $s=R/h^2$, the sustained selection differential in Fig 1.

Table S3. A) Parameter estimates for $\dot{T}_{\max}$ and significance of parameters (* P<0.05, ** P<0.01, *** P<0.001), partitioned by month (based on 99 Mexican weather stations (see Table S2 for geographical coordinates), N=1178 station × months and N=31552 days of records). **B)** Fitted surface for T_{max} in 2009.

These two sets of equations (Table S3A and S3B) for the rate of temperature change ($\dot{T}_{\max}$) across Mexico and starting point for temperature in 2009 ($T_{max,2009}$) were used to forecast temperature change and impacts on extinction into the future (see text and below, for the ground-truth of the extinction model). The positive and linear effects of latitude and elevation indicate that climate change expressed as $\dot{T}_{\max}$ has been most rapid in the north and at high elevation, even though the entire region of Mexico has increased in temperature (1973-2008) (e.g., Figure S1 shows a general warming across all of Mexico, $\dot{T}_{\max} > 0$). In addition, negative effects of longitude indicate that eastern regions of Mexico (e.g., the Yucatán peninsula and Atlantic slopes) have warmed more rapidly than western regions. Finally, the significant elevational and latitudinal effects on $\dot{T}_{\max}$ tend to be concentrated in winter-spring months (Jan-May) with only one summer month registering significant change (July; Table S3A). Longitudinal effects on $\dot{T}_{\max}$ are also concentrated in winter-spring months (January-May) and fall months (August-December) (Table S3A). A similar analysis for precipitation (1973-2008) has absolutely no significant geographical terms (not shown) indicating that climate change has not altered rainfall patterns in México.

We tested for the seasonality of climate change (Table S2A) and extinction risk (Table S1). Most stations where $\dot{T}_{\max,j}$ was measured are not next to study sites so we estimated monthly $\dot{T}_{\max,j}$, for those sites *i*, using geo-referenced climate equations [$\dot{T}_{\max}(lat, long, elev)$, Table S3A]. A multiple regression of PICs for extinction and $\dot{T}_{\max,j}$ by month revealed significant effects for February (t=2.19, d.f.=197, P=0.03), March (t=2.64, P=0.009), April (t=2.74, P=0.007) and September (t=2.34, P=0.02) but no effects during Jun-Aug or Oct-Dec (P>0.16), implicating winter/spring climate change with extinction.

Table S4. T_b and T_{air} for *Sceloporus* lizards. Most data were obtained from Andrew's (*S4*) review. Data collected by the authors are indicated in **boldface**. Most data on Probability[persistence]=lineage survival [e.g., Prob(extinct)=1-Prob(persistence)] were drawn from Table S1, however, extinction records for *S. graciosus* (N=6), *S. occidentalis* (N=6), *S. magister* (N=3), *S. merriami* (N=3), *S. orcutti* (N=1), *S. undulatus* (N=4), *S. variabilis* (N=3), *S. virgatus* (N=2), *S. gadoviae* (N=2), *S. ochoterenae* (N=1), *S. malachiticus* (N=15), *S. woodi* (N=3) are from recent geographical surveys for color polymorphism (no extinctions recorded at any of these sites; Sinervo et al. in preparation).

Table S5. Critical Thermal Maximum (*S6*), CT_{max}, evolves in a correlated fashion with respect to evolved changes in T_b, albeit at a slower rate. An evolutionary increase in T_b by 1.0° C only results in a correlated increase in CT_{max} of 0.51° C based on Phylogenetic Independent Contrasts regression (Figure S3). We analyzed data on CT_{max} for 22 species lizards in the Phrynosomatidae, 11 of which are *Sceloporus* species. We averaged geographic variation in CT_{max} among populations within each species. Average T_b was obtained from Table S2 or from the other sources listed below. We computed phylogenetic independent contrasts (PIC) (Figure S4) using the PDAP (*S25*) module of Mesquite (*S26*), with the phylogeny given in Figure S5. Values for CT_{max} listed below were averaged prior to analysis (T_b average from Table S4 is also listed below).

Table S6. Geo-referenced data (latitude, longitude, elevation [m]) for T_b (N=1372) from the literature for 34 lizard families. We searched Google Scholar using family or generic names and the words preferred temperature, body temperature, T_b, or cloacal temperature. We used historical and revised nomenclature for each family/genus (old nomenclature is in brackets after the reference). We included multiple records of single species, given that T_b's were recorded across a variety of habitats, latitudes and elevations. Thus, our extinction modeling is based on N=587 species T_b's geo-referenced (N=1216 locations) by latitude, longitude and elevation (Fig. S9). In T_b analyses, we included measures of $T_{b,preferred}$ with T_b, given that these values were highly correlated in taxa where both have been measured (R^2=0.587, $F_{1,151}$=210.34, $P<0.00001$). In studies where multiple sites were listed, we included the average T_b across all sites, or if T_b was partitioned by site in the source, we used the average T_b for each site. In our Google Scholar search we strived to obtain broad taxonomic coverage (across all lizard families and genera) and geographic coverage of the world (see Map of sites, below). The latitude, longitude and altitude for each entry were derived from each source (coordinates or verbal descriptions) that were mapped and verified with Google Earth. In a few instances the sources did not provide exact coordinates for all T_b values and supplementary refs (listed below) were used. In one source (ref. *S184, Lit. cited for T_b data*) no geo-referencing was provided for the T_b data, however, supplementary materials in that source provided geo-referencing for DNA samples so we assumed these were also the source of T_bs. Approximately 50% of T_b records are from the New World, and the data set has reasonable coverage from temperature to tropical zones, but species diversity is under-represented in the tropics. Accordingly, we computed estimates of extinction that were weighted by $N_{species}$ in each family (Table 1) to provide unbiased estimates of extinction, assuming a random sample of lizard T_b in each family.

Table S7A. Resurvey data for Liolaemidae (N=128 sites) emphasized resurveys at type localities (denoted by *, or year type was described denoted by **), as well as other locality records (no asterisks). We resurveyed sites on the year indicated. For example, in 2008, we resurveyed the Puerto Deseado, Argentina site where in 1883 Charles Darwin collected *Liolaemus kingii*, *L. bibronii*, and *L. fitzingerii*. When T_b data for a species was not in Table S6, we used a regression equation for altitudinal effects of T_b (data from Table 6: T_b=34.58-0.000491×Alt, P=0.008) to compute extinction predictions in 2009 along with Worldclim.org data for T_{max}. The *L. lutzae* data are also informative on the potential role of habitat disturbance as a confounding factor on extinction risk. We reanalysed disturbance effects noted in ref (*S34*) and found observed extinctions were significantly predicted by the model using logistic regression (predicted status: χ^2=10.4, d.f.=23, P=0.001), but disturbance was only marginally significant (χ^2=3.24, d.f.=23, P=0.07). Goodness-of-fit for observed vs. predicted extinctions, with disturbance effects deleted, was significant (χ^2=8.84, d.f.=1, P=0.003). Goodness-of-fit test for all N=128 resurveyed sites was highly significant (χ^2=32.0, d.f.=1, P<0.0000001). We also ran the model with N=3155 georeferenced sites for Liolaemidae, which confirmed that 5% of all local populations are projected to be currently extinct.

Estimating h_r. Observations on thermoregulatory behaviors of *L. lutzae* indicate that it has evolved an h_r higher than other Liolaemids, given the severity of its current thermal habitat (*S55*). *Liolaemus lutzae* has evolved novel foraging behavior under leaves and detritus to keep out of the sun and limit its T_b. The h_r for *L. lutzae* was estimated from the difference in activity time on sunny days when high T_{soil} limits activity and cloudy days when it can be active all day long. Hot days limit activity by 1.83 h, based on this direct estimate (*S56*). The h_r can also be calibrated from observed extinctions (*c.f.* Mexican *Sceloporus*, see paper), T_{max}, and T_b [34.85ºC at noon (*S55*)], yielding an h_r of 2.0. Despite novel thermoregulatory behaviors that have evolved in *L. lutzae*, the northernmost liolaemid in coastal Brazil, it is currently rapidly going extinct. An h_r of 1.4 (taken from Table 1) was used for other Liolaemidae.

† The year *Phymaturus tenebrosus* was last observed at this site was 2001.

Table S7B. Resurvey sites (N=46) for *Lacerta vivipara* [primary surveys by BH, see sites in (*S35-S43*); MM for Puy Mary (1989), and JC in late 1980s for remaining sites. Resurveys (2002-2009) were done by BS, BH, DBM, VL, MM and JC from 2002-2009. Resurveys have pinpointed the date of 12 extinctions to the period after 2000, when climate has warmed rapidly in Europe (*S44*). We used the regression of T_b on altitude (T_b=31.492-0.002005 × Alt, P<0.002, data from Table S6), and h_r=3.1 (value from Table 1). The goodness-of-fit of observed and predicted extinctions is significant (χ^2= 24.4, d.f.=1, P<0.00001).

Table S7C. Resurvey data for species in the *Egernia* Group (Scincidae: *Liopholis* + *Egernia*). Dates of original survey and resurvey (i.e., after 2000) are given in refs. (*S57-S59*). Our model exactly predicts the 3 observed extinctions in *L. slateri* and 8 sites where it persists today (χ^2=12.9, d.f.=1, P<0.0001). We compared *L. slateri* to other *Egernia* and *Liopholis* spp. from Table S6. None of these other species faces 2009 extinction risk (goodness-of-fit χ^2=17.8, d.f.=1, P<0.0001). We assumed *L. slateri* had the same T_b as *L. whitii*, the most closely related species. We estimated h_r=5.15 by goodness-of-fit methods used for Mexican *Sceloporus* (e.g., calibration value that maximizes the fit between observed and predicted extinctions). We also ran a model with N=2481 georeferenced sites to estimate species extinction, which confirmed that those species sympatric with *L. slateri* are going extinct, such as *L. kintorei* (Table S7D).

			Extinction Status	
Species	**Latitude**	**Longitude**	**Observed**	**Predicted**
Liopholis slateri	-24.3333	132.6667	1	1

Egernia stokesi	-28.8870	114.0000	1	1
Egernia stokesii	-31.9000	138.4160	1	1
Egernia striolata	-34.5670	139.5830	1	1
Liopholis whitii	-36.1670	148.4330	1	1
Liopholis whitii	-27.5550	152.2790	1	1

Table S7D Dates and locations of primary surveys of *Liopholis kintorei* are in ref. (*S60*). Data on resurveys of populations (N=29) are from refs. (*S61-S65*). Coordinates were digitized and cross-referenced among sources. Goodness-of-fit for observed and predicted extinctions from our model was significant (goodness-of-fit χ^2=3.93, d.f.=1, P=0.047). The recent and rapid extinctions of *L. kintorei* have remained enigmatic and attributed to fox, feral cats and altered burn regimes, [*L. kintorei* is found in 3-15 year old burns (*S62*)]. Our analysis suggests that extinction of some local populations is likely due to climate change. However, there is a population segment in the Tanami area that is persistent (denoted by * in the Table), but we predict them to be extinct. The model thus poorly predicts extinction status in this local region whereas other areas are well predicted. McAlpin (*S62*) suggests that the Tanami area receives more rainfall relative to other populations, perhaps ameliorating climate change impacts by minimizing deleterious effects of water loss and the costs of thermoregulation. We used a T_b=33.6°C for *L. kintorei* (*S65*) and a value for h_r=6.0 from Table 1, which incidentally maximizes the goodness-of-fit criterion between observed and predicted extinctions. There are no detailed studies from which we can compute h_r directly from behavior, as was done for *Liolaemus lutzae* (see Table S7A), and *Sceloporus* lizards (see paper). [N.B. Pearson et al. (*S66*) list 3 sites surveyed in 1997, however these exact sites have not been resurveyed since. McAlpin (*S62*) indicates that the region between Patjarr and Warburton currently support many populations, and thus we assumed the 3 Warburton sites noted by Cogger et al. (*S60*) are persistent]. More recent surveys by McAlpin (pers. comm.) suggest that some sites recorded as extinct in the literature (and thus in the Table) may have recently (2009-2010) been re-colonized. Therefore, in the case of the *L. kintorei*, the extinction of local populations is likely to have a meta-population dynamic of local extinctions and period re-colonization events.

Species	Locale or Ref.	Lat	Lon	Elev.	Extinction Obs.	Extinction Pred.

Table S8. Comparison of local population extinction and species extinction for 2080 and 2050 for the five-continent validation.

2080 Extinctions:

Region: Taxon		2080 Local Extinction Probability	$N_{species}$	2080 Total Extinction Probability
North America: *Sceloporus* species		0.54	48	0.58
Europe: Lacertidae, *L. vivipara* mtDNA clades		0.56	6	0.50
South America Liolaemiadae	*Liolaemus*	0.13	63	0.10
	Phymaturus	0.73	13	0.69
Africa: Gerrhosauridae+Cordylidae		0.17	66	0.08
Australia: Egernia Group Species		0.10	10	0.20

2050 Extinctions:

Region: Taxon		2050 Local Extinction Probability	$N_{species}$	2050 Total Extinction Probability
North America: *Sceloporus* species		0.54	48	0.13
Europe: Lacertidae, *L. vivipara* mtDNA clades		0.56	6	0.17
South America Liolaemiadae	*Liolaemus*	0.07	63	0.05
	Phymaturus	0.68	13	0.31
Africa: Gerrhosauridae+Cordylidae		0.03	66	0.02
Australia: Egernia Group Species		0.06	10	0.10
